

Slide 3

Parallelization — *Finding Concurrency*

- Obvious decomposition for simple approach is task-based, with one task per point. Tasks are completely independent.
- For block-based approach, may make more sense to think in terms of decomposing data into blocks; then tasks correspond to computing blocks of *C*. Again, though, they're independent.

Slide 4

Slide 6

Parallelization — *Algorithm Structure* (Distributed Memory)

• For distributed memory we have to think about how to distribute C and how to duplicate/distribute A and B. Might work better to think in terms of block-based approach and data decomposition — so *Geometric Decomposition* might be a better fit.

Slide 7

- Key design decisions here are how to decompose data and assign chunks to UEs, and then how to manage synchronization/communication for update operation.
- Probably makes sense to decompose data so we can assign one block of C to each UE — amount of work per block is pretty much constant.

Parallelization — *Algorithm Structure* (Distributed Memory), Continued

• For each block of *C*, computation can be thought of a sequence of update operations, each involving a different combination of blocks of *A* and *B*. (Compare how this fits overall idea of *Geometric Decomposition* with how heat-diffusion example fits.)

Slide 8

 This tells us what kind of communication we need. Simple approach is to broadcast two blocks at each step, one for "row" and one for "column". More complex, but more efficient, version involves rotating blocks among processes.

- For program structure, we probably want *SPMD* (especially if using MPI or similar programming environment).
- *Distributed Array* is relevant, especially for parts of sample/test program that initialize and print array (since they use each array element's global indices).

Slide 9

Parallelization — Code (Distributed Memory) If we distribute all three arrays (which seems like a good idea), we have to make changes in code to initialize and print as well as matrix-multiplication. As is often the case with programs using *Distributed Array*, the ideas are simple but the code inclined to be messy. For actual multiplication, each process will update one "chunk", doing the same computation done in the block-based sequential program, but with communication operations to broadcast two blocks per step. (Look at code.)
